antibody concentration. See (14, 27). Because the fluorescence of an artificial-fluorescent complex is efficiently quenched by rapid electron transfer from either a cytochrome tryptophan or tyrosine to single excited fluorescent (27). We conclude that the very bright blue fluorescence of EFP2-19G2-1 is attributable to electron-hole recombination of the Trp-stilbene charge transfer excited state held in the rigid EFP2-19G2 matrix that disallows nonradiative decay.

Protein luminescence (22) only rarely (if ever) occurs by electron-hole recombination in a charge-transfer excited state embedded in a polypeptide matrix. The distinctive photophysical properties of the antibody-stilbene complex have already been exploited in chiral sensing for high-throughput screening for the evaluation of catalysis in asymmetric synthesis (23, 24), sensing mercury (25), DNA hybridization assays (26, 27), and for analysis of accessible cysteine residues on viral surfaces (28). The programmed generation of antibodies against other chiralophores may yield novel protein-based systems with similar charge recombination-induced lumi-

Land Clearing and the Biofuel Carbon Debt

Joseph Fargione,¹ Jason Hill,^{2,3} David Tilman,^{2,3} Stephen Polasky,^{2,3} Peter Mathebaum²

Increasing energy use, climate change, and carbon dioxide (CO₂) emissions from fossil fuels make switching to low-carbon fuels a high priority. Biofuels are a potential low-carbon energy source, but whether biofuels offer

rainforests, peatlands, and the Southeast Asia, and that 10 times more CO₂ than the biomass grown on regular or no carbon debt and is

Use of U.S. Croplands for Biofuels Increases Greenhouse Gases Through Emissions from Land-Use Change

Timothy Searchinger,^{1,2} Ralph Heimlich,² R. A. Houghton,³ Fengqin Dong,⁴ Junmi Lobatto,⁴ Jacinto Fabiosa,⁴ Simla Tokgoz,⁴ Dermot Hayes,⁴ Teh-Hsing Yu⁴

Most prior studies have found that substituting biofuels for gasoline will reduce greenhouse gases because biofuels sequester carbon through the growth of the feedstock. These analyses have failed to count the carbon emissions that occur as farmers worldwide respond to higher prices and convert forest and grassland to new cropland to replace the grain (or cropland) diverted to biofuels. By using a worldwide agricultural model to estimate emissions from land-use change, we found that corn-based ethanol, instead of producing a 20% savings, nearly doubles greenhouse emissions over 30 years and increases greenhouse gases for 167 years. Biofuels from switchgrass, if grown on U.S. corn lands, increase emissions by 50%. This result raises concerns about large biofuel mandates and highlights the value of using waste products.

in the case of cropland, carbohydrates, proteins, and fat), dedicating land to biofuels can potentially reduce GHGs only if doing so increases the carbon benefit of land. Proper accounting must reflect the net impact on the carbon benefit of land, not merely count the gross benefit of using land for biofuels. Technically, to generate greenhouse benefits, the carbon generated in land to displace fossil fuels (the carbon uptake credit) must exceed the carbon storage and sequestration given up directly or indirectly by changing land uses (the emissions from land-use change) (Table 1).

Many prior studies have acknowledged but failed to count emissions from land-use change because they are difficult to quantify (7). One prior quantification lacked formal agricultural modeling and other features of our analysis (1, 10). To estimate land-use changes, we used a worldwide model to project increases in cropland in all major temperate and major crops by country or region for as well as changes in dairy and livestock
